2. A* and IDA*
3. Local Search Methods
4. Genetic Algorithms
Search procedures differ in the way they determine the next node to expand.

**Uninformed Search:** Rigid procedure with no knowledge of the cost of a given node to the goal.

**Informed Search:** Knowledge of the worth of expanding a node $n$ is given in the form of an *evaluation function* $f(n)$, which assigns a real number to each node. Mostly, $f(n)$ includes as a component a *heuristic function* $h(n)$, which estimates the costs of the cheapest path from $n$ to the goal.

**Best-First Search:** Informed search procedure that expands the node with the “best” $f$-value first.
General Algorithm

function TREE-SEARCH(\textit{problem}) \textbf{returns} a solution, or failure
initialize the frontier using the initial state of \textit{problem}
loop do
    if the frontier is empty then return failure
    choose a leaf node and remove it from the frontier
    if the node contains a goal state then return the corresponding solution
    expand the chosen node, adding the resulting nodes to the frontier

Best-first search is an instance of the general \texttt{TREE-SEARCH} algorithm in which \textit{frontier} is a priority queue ordered by an evaluation function \(f\).

When \(f\) is always correct, we do not need to search!
Greedy Search

A possible way to judge the “worth” of a node is to estimate its path-costs to the goal.

\[ h(n) = \text{estimated path-costs from } n \text{ to the goal} \]

The only real restriction is that \( h(n) = 0 \) if \( n \) is a goal.

A best-first search using \( h(n) \) as the evaluation function, i.e., \( f(n) = h(n) \) is called a greedy search.

Example: route-finding problem:
\[ h(n) = \]
A possible way to judge the “worth” of a node is to estimate its path-costs to the goal.

\[ h(n) = \text{estimated path-costs from } n \text{ to the goal} \]

The only real restriction is that \( h(n) = 0 \) if \( n \) is a goal.

A best-first search using \( h(n) \) as the evaluation function, i.e., \( f(n) = h(n) \) is called a greedy search.

Example: route-finding problem:
\( h(n) = \text{straight-line distance from } n \text{ to the goal} \)
The evaluation function $h$ in greedy searches is also called a *heuristic* function or simply a *heuristic*.

- The word *heuristic* is derived from the Greek word ευρισκείν (note also: ευρηκα!)
- The mathematician Polya introduced the word in the context of problem solving techniques.
- In AI it has two meanings:
  - Heuristics are fast but in certain situations incomplete methods for problem-solving [Newell, Shaw, Simon 1963] (The greedy search is actually generally incomplete).
  - Heuristics are methods that improve the search in the average-case.

$\rightarrow$ In all cases, the heuristic is *problem-specific* and *focuses* the search!
Greedy Search Example

Greedy Search - Properties

- a good heuristic might reduce search time drastically
- non-optimal
- incomplete
- graph-search version is complete only in finite spaces

Can we do better?
A*: Minimization of the Estimated Path Costs

A* combines the greedy search with the uniform-search strategy: Always expand node with lowest $f(n)$ first, where

$g(n) =$ actual cost from the initial state to $n$.

$h(n) =$ estimated cost from $n$ to the next goal.

$f(n) = g(n) + h(n),$

the estimated cost of the cheapest solution through $n$.

Let $h^*(n)$ be the actual cost of the optimal path from $n$ to the next goal. $h$ is admissible if the following holds for all $n$:

$h(n) \leq h^*(n)$

We require that for A*, $h$ is admissible (example: straight-line distance is admissible).

In other words, $h$ is an optimistic estimate of the costs that actually occur.
A* Search Example

A* Search from Arad to Bucharest

(e) After expanding Fagaras

(f) After expanding Pitesti
Example: Path Planning for Robots in a Grid-World
**Optimality of A**

**Claim:** The first solution found has the minimum path cost.

**Proof:** Suppose there exists a goal node \( G \) with optimal path cost \( f^* \), but A* has found another node \( G_2 \) with \( g(G_2) > f^* \).
Let $n$ be a node on the path from the start to $G$ that has not yet been expanded. Since $h$ is admissible, we have

$$f(n) \leq f^*.$$ 

Since $n$ was not expanded before $G_2$, the following must hold:

$$f(G_2) \leq f(n)$$

and

$$f(G_2) \leq f^*.$$ 

It follows from $h(G_2) = 0$ that

$$g(G_2) \leq f^*.$$ 

→ Contradicts the assumption!
Completeness:

If a solution exists, A* will find it provided that (1) every node has a finite number of successor nodes, and (2) there exists a positive constant $\delta > 0$ such that every step has at least cost $\delta$.

$\rightarrow$ there exists only a finite number of nodes $n$ with $f(n) \leq f^*$. 

Complexity:

In general, still exponential in the path length of the solution (space, time)

More refined complexity results depend on the assumptions made, e.g. on the quality of the heuristic function. Example:

In the case in which $|h^*(n) - h(n)| \leq O(\log(h^*(n)))$, only one goal state exists, and the search graph is a tree, a sub-exponential number of nodes will be expanded [Gaschnig, 1977, Helmert & Roeger, 2008].
Heuristic Function Example

Start State

Goal State

$h_1$ = the number of tiles in the wrong position

$h_2$ = the sum of the distances of the tiles from their goal positions (Manhattan distance)
Heuristic Function Example

\[ h_1 = \text{the number of tiles in the wrong position} \]
Heuristic Function Example

\[ h_1 = \text{the number of tiles in the wrong position} \]
\[ h_2 = \text{the sum of the distances of the tiles from their goal positions (Manhattan distance)} \]
**Empirical Evaluation**

- $d =$ distance from goal
- Average over 100 instances

A* in general still suffers from exponential memory growth. Therefore, several refinements have been suggested:

- iterative-deepening A*, where the f-costs are used to define the cutoff (rather than the depth of the search tree): IDA*

- Recursive Best First Search (RBFS): introduces a variable $f\_limit$ to keep track of the best alternative path available from any ancestor of the current node. If the current node exceeds this limit, recursion unwinds back to the alternative path.

- other alternatives memory-bounded A* (MA*), simplified MA*, and SMA*.
Local Search Methods

- In many problems, it is unimportant how the goal is reached - only the goal itself matters (8-queens problem, VLSI Layout, TSP).
- If in addition a quality measure for states is given, a **local search** can be used to find solutions.
- operates using a single current node (rather than multiple paths)
- use very little memory
- Idea: Begin with a randomly-chosen configuration and improve on it stepwise → **Hill Climbing**.
- note: can be used for maximization or minimization respectively (see 8 queens example)
Example state with heuristic cost estimate $h = 17$ (counts the number of pairs threatening each other directly or indirectly).
function HILL-CLIMBING (problem) returns a state that is a local maximum

current ← MAKE-NODE(problem.INITIAL-STATE)

loop do
    neighbor ← a highest-valued successor of current
    if neighbor.VALUE ≤ current.VALUE then return current.STATE
    current ← neighbor
Possible realization of a hill-climbing algorithm:
Select a column and move the queen to the square with the fewest conflicts.
Problems with Local Search Methods

- **Local maxima**: The algorithm finds a sub-optimal solution.
- **Plateaus**: Here, the algorithm can only explore at random.
- **Ridges**: Similar to plateaus.

**Solutions:**

- *Start over* when no progress is being made.
- “Inject noise” → random walk

Which strategies (with which parameters) are successful (within a problem class) can usually only empirically be determined.
Local minimum \((h = 1)\) of the 8-Queens Problem. Every successor has a higher cost.
Illustration of the ridge problem

The grid of states (dark circles) is superimposed on a ridge rising from left to right, creating a sequence of local maxima, that are not directly connected to each other. From each local maximum, all the available actions point downhill.
8 queens has about $8^8 \approx 17 \text{ million}$ states. Starting from a random initialization, hill-climbing directly finds a solution in about 14% of the cases. Needs in average only 4 steps!

Better algorithm: allow sideways moves (no improvement), but restrict the number of moves (avoid infinite loops!).

E.g.: max. 100 moves: solves 94%, number of steps raises to 21 steps for successful instances and 64 for each failure.
Simulated Annealing

In the simulated annealing algorithm, “noise” is injected systematically: first a lot, then gradually less.

```
function SIMULATED-ANNEALING(problem, schedule) returns a solution state
  inputs: problem, a problem
            schedule, a mapping from time to “temperature”
  current ← MAKE-NODE(problem.INITIAL-STATE)
  for t = 1 to ∞ do
    T ← schedule(t)
    if T = 0 then return current
    next ← a randomly selected successor of current
    ΔE ← next.VALUE – current.VALUE
    if ΔE > 0 then current ← next
    else current ← next only with probability e^{ΔE/T}
```

Has been used since the early 80’s for VSLI layout and other optimization problems.
Evolution appears to be very successful at finding good solutions.

**Idea:** Similar to evolution, we search for solutions by “crossing”, “mutating”, and “selecting” successful solutions.

**Ingredients:**
- Coding of a solution into a string of symbols or bit-string
- A fitness function to judge the worth of configurations
- A population of configurations

**Example:** 8-queens problem as a chain of 8 numbers. Fitness is judged by the number of non-attacks. The population consists of a set of arrangements of queens.
Selection, Mutation, and Crossing

Many variations:
how selection will be applied, what type of cross-over operators will be used, etc.

Selection of individuals according to a fitness function and pairing

Calculation of the breaking points and recombination

According to a given probability elements in the string are modified.
Heuristics focus the search

Best-first search expands the node with the highest worth (defined by any measure) first.

With the minimization of the evaluated costs to the goal $h$ we obtain a greedy search.

The minimization of $f(n) = g(n) + h(n)$ combines uniform and greedy searches. When $h(n)$ is admissible, i.e., $h^*$ is never overestimated, we obtain the A* search, which is complete and optimal.

IDA* is a combination of the iterative-deepening and A* searches.

Local search methods only ever work on one state, attempting to improve it step-wise.

Genetic algorithms imitate evolution by combining good solutions.
