Introduction to search algorithms for planning

Our plan for the next lectures

Choices to make:

1. search direction: progression/regression/both
   ⇝ previous chapter
2. search space representation: states/sets of states
   ⇝ previous chapter
3. search algorithm: uninformed/heuristic; systematic/local
   ⇝ this chapter
4. search control: heuristics, pruning techniques
   ⇝ next chapters

Search

- Search algorithms are used to find solutions (plans) for transition systems in general, not just for planning tasks.
- Planning is one application of search among many.
- In this chapter, we describe some popular and/or representative search algorithms, and (the basics of) how they apply to planning.
- Most of this is review of material that should be known (details: Russell and Norvig's textbook).

Search states vs. search nodes

In search, one distinguishes:

- search states s $\rightsquigarrow$ states (vertices) of the transition system
- search nodes σ $\rightsquigarrow$ search states plus information on where/when/how they are encountered during search

What is in a search node?

Different search algorithms store different information in a search node σ, but typical information includes:

- $state(\sigma)$: associated search state
- $parent(\sigma)$: pointer to search node from which σ is reached
- $action(\sigma)$: action leading from $state(parent(\sigma))$ to $state(\sigma)$
- $g(\sigma)$: cost of σ (length of path from the root node)

For the root node, $parent(\sigma)$ and $action(\sigma)$ are undefined.

Search states vs. planning states

Search states $\neq$ (planning) states:

- Search states don't have to correspond to states in the planning sense.
  - progression: search states $\approx$ (planning) states
  - regression: search states $\approx$ sets of states (formulae)
- Search algorithms for planning where search states are planning states are called state-space search algorithms.
- Strictly speaking, regression is not an example of state-space search, although the term is often used loosely.
- However, we will put the emphasis on progression, which is almost always state-space search.

Required ingredients for search

A general search algorithm can be applied to any transition system for which we can define the following three operations:

- init(): generate the initial state
- is-goal(s): test if a given state is a goal state
- succ(s): generate the set of successor states of state s, along with the operators through which they are reached (represented as pairs $\langle o, s' \rangle$ of operators and states)

Together, these three functions form a search space (a very similar notion to a transition system).

Search for planning: progression

Let $\Pi = \langle A, I, O, \gamma \rangle$ be a planning task.

Search space for progression search

states: all states of Π (assignments to A)

- init() = I
- is-goal(s) = $\begin{cases} \textbf{true} & \text{if } s \models \gamma \\ \textbf{false} & \text{otherwise} \end{cases}$
- succ(s) = $\{\langle o, s' \rangle \mid \text{applicable } o \in O, s' = app_o(s)\}$

Search for planning: regression

Let $\Pi = \langle A, I, O, \gamma \rangle$ be a planning task.

Search space for regression search

states: all formulae over A (how many?)

- init() = γ
- is-goal(φ) = $\begin{cases} \textbf{true} & \text{if } I \models \varphi \\ \textbf{false} & \text{otherwise} \end{cases}$
- succ(φ) = $\{\langle o, \varphi' \rangle \mid o \in O,$
  $\varphi' = regr_o(\varphi), \varphi' \text{ is satisfiable}\}$
  (modified if splitting is used)

Classification of search algorithms

uninformed search vs. heuristic search:

- uninformed search algorithms only use the basic ingredients for general search algorithms
- heuristic search algorithms additionally use heuristic functions which estimate how close a node is to the goal

systematic search vs. local search:

- systematic algorithms consider a large number of search nodes simultaneously
- local search algorithms work with one (or a few) candidate solutions (search nodes) at a time
- not a black-and-white distinction; there are crossbreeds (e. g., enforced hill-climbing)

Classification: what works where in planning?

uninformed vs. heuristic search:

- For satisficing planning, heuristic search vastly outperforms uninformed algorithms on most domains.
- For optimal planning, the difference is less pronounced.

systematic search vs. local search:

- For satisficing planning, the most successful algorithms are somewhere between the two extremes.
- For optimal planning, systematic algorithms are required.

Common procedures for search algorithms

Before we describe the different search algorithms, we introduce three procedures used by all of them:

- make-root-node: Create a search node without parent.
- make-node: Create a search node for a state generated as the successor of another state.
- extract-solution: Extract a solution from a search node representing a goal state.

Procedure make-root-node

make-root-node: Create a search node without parent.

Procedure make-root-node

def make-root-node(s):
  σ := **new** node
  $state(\sigma) := s$
  $parent(\sigma)$:= undefined
  $action(\sigma)$:= undefined
  $g(\sigma) := 0$
  return σ

Procedure make-node

make-node: Create a search node for a state generated as the successor of another state.

Procedure make-node

def make-node(σ, o, s):
    σ' := **new** node
    $state(\sigma') := s$
    $parent(\sigma') := \sigma$
    $action(\sigma') := o$
    $g(\sigma') := g(\sigma) + 1$
    return σ'

Procedure extract-solution

extract-solution: Extract a solution from a search node representing a goal state.

Procedure extract-solution

def extract-solution(σ):
    solution := **new** list
    while *parent*(σ) is defined:
        solution.push-front(*action*(σ))
        σ := *parent*(σ)
    return *solution*

Uninformed search algorithms

Uninformed search algorithms

- Uninformed algorithms are less relevant for planning than heuristic ones, so we keep their discussion brief.
- Uninformed algorithms are mostly interesting to us because we can compare and contrast them to related heuristic search algorithms.

Popular uninformed systematic search algorithms:

- breadth-first search
- depth-first search
- iterated depth-first search

Popular uninformed local search algorithms:

- random walk

Breadth-first search without duplicate detection

Breadth-first search

queue := **new** fifo-queue
queue.push-back(make-root-node(init()))
while not *queue*.empty():
  σ = *queue*.pop-front()
  if is-goal(state(σ)):
    return extract-solution(σ)
  for each $\langle o, s \rangle \in$ succ(*state*(σ)):
    σ' := make-node(σ, o, s)
    queue.push-back(σ')
return unsolvable

- Possible improvement: duplicate detection (see next slide).
- Another possible improvement: test if σ' is a goal node; if so, terminate immediately. (We don't do this because it obscures the similarity to some of the later algorithms.)

Breadth-first search with duplicate detection

Breadth-first search with duplicate detection

queue := **new** fifo-queue
queue.push-back(make-root-node(init()))
closed := $\emptyset$
while not *queue*.empty():
    σ = *queue*.pop-front()
    if $state(\sigma) \notin closed$:
        $closed := closed \cup \{state(\sigma)\}$
        if is-goal(state(σ)):
            return extract-solution(σ)
        for each $\langle o, s\rangle \in$ succ($state(\sigma)$):
            σ' := make-node(σ, o, s)
            queue.push-back(σ')
return unsolvable

Breadth-first search with duplicate detection

Breadth-first search with duplicate detection

```
queue := new fifo-queue
queue.push-back(make-root-node(init()))
closed := ∅
while not queue.empty():
    σ = queue.pop-front()
    if state(σ) ∉ closed:
        closed := closed ∪ {state(σ)}
        if is-goal(state(σ)):
            return extract-solution(σ)
        for each ⟨o,s⟩ ∈ succ(state(σ)):
            σ′ := make-node(σ,o,s)
            queue.push-back(σ′)
return unsolvable
```

Random walk

Random walk

σ := make-root-node(init())
forever:
    if is-goal(state(σ)):
        return extract-solution(σ)
    Choose a random element $\langle o, s \rangle$ from succ(state(σ)).
    σ := make-node(σ, o, s)

- The algorithm usually does not find any solutions, unless almost every sequence of actions is a plan.
- Often, it runs indefinitely without making progress.
- It can also fail by reaching a dead end, a state with no successors. This is a weakness of many local search approaches.

Heuristic search algorithms

Heuristic search algorithms: systematic

- Heuristic search algorithms are the most common and overall most successful algorithms for classical planning.

Popular systematic heuristic search algorithms:

- greedy best-first search
- A^*
- weighted A^*
- IDA^*
- depth-first branch-and-bound search
- ...

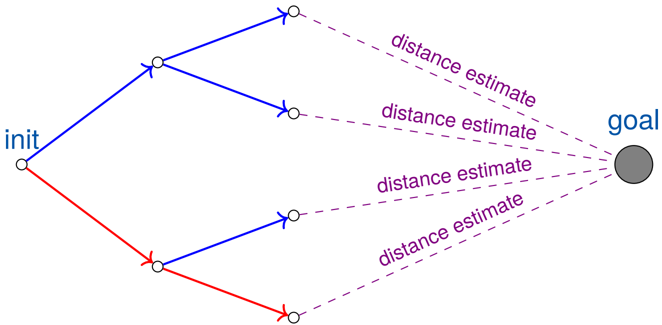
Heuristic search algorithms: local

- Heuristic search algorithms are the most common and overall most successful algorithms for classical planning.

Popular heuristic local search algorithms:

- hill-climbing
- enforced hill-climbing
- beam search
- tabu search
- genetic algorithms
- simulated annealing
- ...

Heuristic search: idea



Required ingredients for heuristic search

A heuristic search algorithm requires one more operation in addition to the definition of a search space.

Definition (heuristic function)

Let Σ be the set of nodes of a given search space.
A heuristic function or heuristic (for that search space) is a function $h : \Sigma \to \mathbb{N}_0 \cup \{\infty\}$.

The value $h(\sigma)$ is called the heuristic estimate or heuristic value of heuristic h for node σ. It is supposed to estimate the distance from σ to the nearest goal node.

What exactly is a heuristic estimate?

What does it mean that *h* “estimates the goal distance”?

- For most heuristic search algorithms, *h* does not need to have any strong properties for the algorithm to work (= be correct and complete).
- However, the efficiency of the algorithm closely relates to how accurately *h* reflects the actual goal distance.
- For some algorithms, like A*, we can prove strong formal relationships between properties of *h* and properties of the algorithm (optimality, dominance, run-time for bounded error, ...)
- For other search algorithms, “it works well in practice” is often as good an analysis as one gets.

Heuristics applied to nodes or states?

- Most texts apply heuristic functions to states, not nodes.
- This is slightly less general than our definition:
  - Given a state heuristic h, we can define an equivalent node heuristic as $h'(\sigma) := h(state(\sigma))$.
  - The opposite is not possible. (Why not?)
- There is good justification for only allowing state-defined heuristics: why should the estimated distance to the goal depend on how we ended up in a given state s?
- We call heuristics which don't just depend on $state(\sigma)$ pseudo-heuristics.
- In practice there are sometimes good reasons to have the heuristic value depend on the generating path of σ (e. g., landmark pseudo-heuristic, Richter et al. 2008).

Perfect heuristic

Let Σ be the set of nodes of a given search space.

Definition (optimal/perfect heuristic)

The optimal or perfect heuristic of a search space is the heuristic h^* which maps each search node σ to the length of a shortest path from $state(\sigma)$ to any goal state.

Note: $h^*(\sigma) = \infty$ iff no goal state is reachable from σ.

Properties of heuristics

A heuristic h is called

- safe if $h^*(\sigma) = \infty$ for all $\sigma \in \Sigma$ with $h(\sigma) = \infty$
- goal-aware if $h(\sigma) = 0$ for all goal nodes $\sigma \in \Sigma$
- admissible if $h(\sigma) \leq h^*(\sigma)$ for all nodes $\sigma \in \Sigma$
- consistent if $h(\sigma) \leq h(\sigma') + 1$ for all nodes $\sigma, \sigma' \in \Sigma$ such that σ' is a successor of σ.[1]

Relationships?

[1] or: $h(\sigma) \leq h(\sigma') + cost(\sigma, \sigma')$ for non-unit costs, where $cost(\sigma, \sigma')$ is the cost of the transition from σ to σ'.

UNI FREIBURG

Greedy best-first search (with duplicate detection)

```
open := new min-heap ordered by (σ ↦ h(σ))
open.insert(make-root-node(init()))
closed := ∅
while not open.empty():
    σ = open.pop-min()
    if state(σ) ∉ closed:
        closed := closed ∪ {state(σ)}
        if is-goal(state(σ)):
            return extract-solution(σ)
        for each ⟨o,s⟩ ∈ succ(state(σ)):
            σ' := make-node(σ,o,s)
            if h(σ') < ∞:
                open.insert(σ')
return unsolvable
```

Properties of greedy best-first search

- one of the three most commonly used algorithms for satisficing planning
- complete for safe heuristics (due to duplicate detection)
- suboptimal unless h satisfies some very strong assumptions (similar to being perfect)
- invariant under all strictly monotonic transformations of h (e. g., scaling with a positive constant or adding a constant)

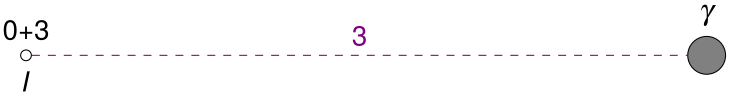
UNI FREIBURG

A* (with duplicate detection and reopening)

open := **new** min-heap ordered by $(\sigma \mapsto g(\sigma) + h(\sigma))$
open.insert(make-root-node(init()))
closed := $\emptyset$
distance := $\emptyset$
while not *open*.empty():
    σ = *open*.pop-min()
    if $state(\sigma) \notin closed$ **or** $g(\sigma) < distance(state(\sigma))$:
        $closed := closed \cup \{state(\sigma)\}$
        $distance(state(\sigma)) := g(\sigma)$
        if is-goal(state(σ)):
            return extract-solution(σ)
        for each $\langle o, s\rangle \in$ succ($state(\sigma)$):
            σ' := make-node(σ, o, s)
            if $h(\sigma') < \infty$: *open*.insert(σ')
return unsolvable

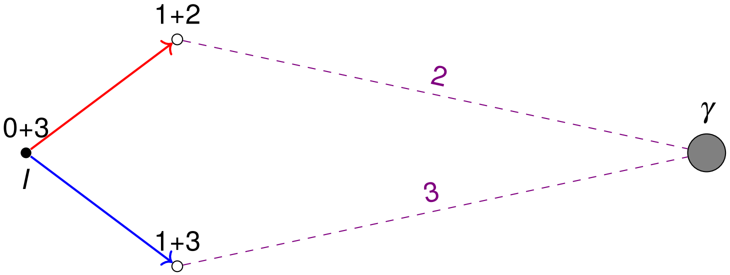
A* example

Example



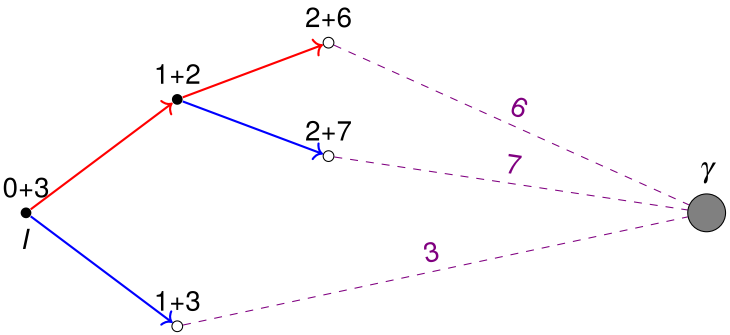
A* example

Example



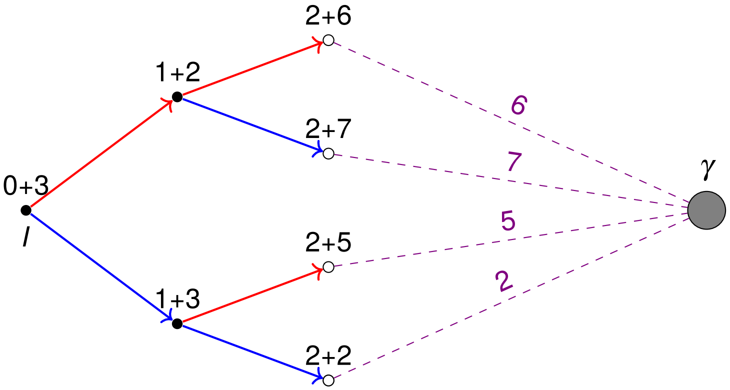
A^* example

Example



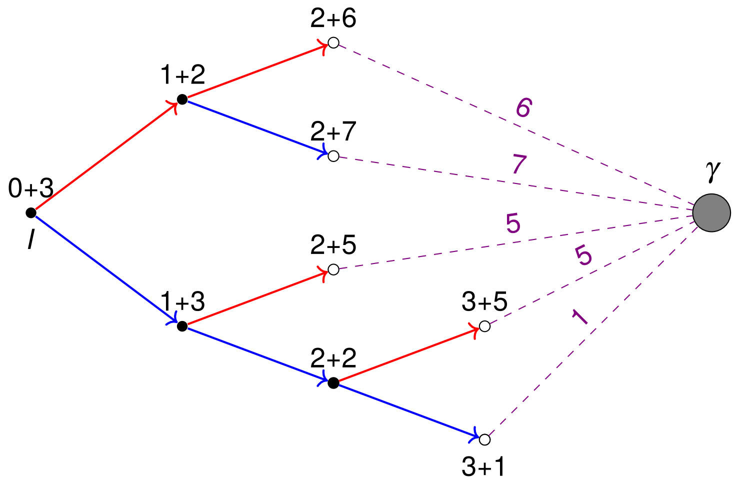
A* example

Example



A* example

Example



Terminology for A*

- *f* value of a node: defined by $f(\sigma) := g(\sigma) + h(\sigma)$
- generated nodes: nodes inserted into *open* at some point
- expanded nodes: nodes σ popped from *open* for which the test against *closed* and *distance* succeeds
- reexpanded nodes: expanded nodes for which $state(\sigma) \in closed$ upon expansion (also called reopened nodes)

Properties of A*

- the most commonly used algorithm for optimal planning
- rarely used for satisficing planning
- complete for safe heuristics (even without duplicate detection)
- optimal if *h* is admissible (even without duplicate detection)
- never reopens nodes if *h* is consistent

Implementation notes:

- in the heap-ordering procedure, it is considered a good idea to break ties in favour of lower *h* values
- can simplify algorithm if we know that we only have to deal with consistent heuristics
- common, hard to spot bug: test membership in *closed* at the wrong time

Weighted A*

Weighted A* (with duplicate detection and reopening)

open := **new** min-heap ordered by $(\sigma \mapsto g(\sigma) + W \cdot h(\sigma))$
open.insert(make-root-node(init()))
closed := $\emptyset$
distance := $\emptyset$
while not *open*.empty():
    σ = *open*.pop-min()
    if $state(\sigma) \notin closed$ **or** $g(\sigma) < distance(state(\sigma))$:
        $closed := closed \cup \{state(\sigma)\}$
        $distance(\sigma) := g(\sigma)$
        if is-goal(state(σ)):
            return extract-solution(σ)
        for each $\langle o, s\rangle \in$ succ($state(\sigma)$):
            σ' := make-node(σ, o, s)
            if $h(\sigma') < \infty$: *open*.insert(σ')
return unsolvable

Properties of weighted A*

The weight $W \in \mathbb{R}_0^+$ is a parameter of the algorithm.

- for $W = 0$, behaves like breadth-first search
- for $W = 1$, behaves like A*
- for $W \to \infty$, behaves like greedy best-first search

Properties:

- one of the most commonly used algorithms for satisficing planning
- for $W > 1$, can prove similar properties to A*, replacing optimal with bounded suboptimal: generated solutions are at most a factor W as long as optimal ones

Hill-climbing

Hill-climbing

σ := make-root-node(init())
forever:
    if is-goal(state(σ)):
        return extract-solution(σ)
    Σ' := $\{$ make-node(σ, o, s) $|$ $\langle o, s\rangle \in$ succ(state(σ)) $\}$
    σ := an element of Σ' minimizing h (random tie breaking)

- can easily get stuck in local minima where immediate improvements of $h(\sigma)$ are not possible
- many variations: tie-breaking strategies, restarts

Enforced hill-climbing: procedure improve

def *improve*(σ_0):
    queue := **new** fifo-queue
    queue.push-back(σ_0)
    closed := $\emptyset$
    while not *queue*.empty():
        σ = *queue*.pop-front()
        if $state(\sigma) \notin closed$:
            $closed := closed \cup \{state(\sigma)\}$
            if $h(\sigma) < h(\sigma_0)$:
                return σ
            for each $\langle o, s \rangle \in$ succ($state(\sigma)$):
                σ' := make-node(σ, o, s)
                queue.push-back(σ')
    fail

$\rightsquigarrow$ breadth-first search for more promising node than σ_0

Enforced hill-climbing (ctd.)

Enforced hill-climbing

σ := make-root-node(init())
while not is-goal(state(σ)):
    σ := improve(σ)
return extract-solution(σ)

- one of the three most commonly used algorithms for satisficing planning
- can fail if procedure improve fails (when the goal is unreachable from σ_0)
- complete for undirected search spaces (where the successor relation is symmetric) if $h(\sigma) = 0$ for all goal nodes and only for goal nodes

Summary

- distinguish: planning states, search states, search nodes
  - planning state: situation in the world modelled by the task
  - search state: subproblem remaining to be solved
    - In state-space search (usually progression search), planning states and search states are identical.
    - In regression search, search states usually describe sets of states (“subgoals”).
  - search node: search state + info on “how we got there”
- search algorithms mainly differ in order of node expansion
  - uninformed vs. informed (heuristic) search
  - local vs. systematic search

Summary (ctd.)

- heuristics: estimators for “distance to goal node”
  - usually: the more accurate, the better performance
  - desiderata: safe, goal-aware, admissible, consistent
  - the ideal: perfect heuristic h^*
- most common algorithms for satisficing planning:
  - greedy best-first search
  - weighted A^*
  - enforced hill-climbing
- most common algorithm for optimal planning:
  - A^*
