Abstract. UPPAAL/DMC is an extension of UPPAAL that provides generic heuristics for directed model checking. In this approach, the traversal of the state space is guided by a heuristic function which estimates the distance of a search state to the nearest error state. Our tool combines two recent approaches to design such estimation functions. Both are based on computing an abstraction of the system and using the error distance in this abstraction as the heuristic value. The abstractions, and thus the heuristic functions, are generated fully automatically and do not need any additional user input. UPPAAL/DMC needs less time and memory to find shorter error paths than UPPAAL’s standard search methods.

1 Introduction

UPPAAL/DMC is a tool that accelerates the detection of error states by using the directed model checking approach [4, 5]. Directed model checking tackles the state explosion problem by using a *heuristic function* to influence the *order* in which the search states are explored. A heuristic function h is a function that maps states to integers, estimating the state’s distance to the nearest error state. The search then gives preference to states with lower h value. There are many different ways of doing the latter, all of which we consider the wide-spread method called *greedy search* [8]. There, search nodes are explored in ascending order of their heuristic values. Our empirical results show that this can drastically reduce memory consumption, runtime, and error path length.

Our tool combines two recent approaches to design heuristic functions. Both are based on defining an abstraction of the problem at hand, and taking the heuristic value to be the length of an abstract solution. It is important to note that both techniques are *fully automatic*, i.e., no user intervention is needed to generate the heuristic function. UPPAAL has a built-in heuristic mode, but the specification of the heuristic is entirely up to the user. Inventing a useful heuristic is a tedious job: it requires expert knowledge and a huge amount of time.

2 Heuristics

The next two sections give a brief overview of the abstractions used to build our heuristics, and how heuristic values are assigned to search states.

2.1 Monotonicity Abstraction

Our first heuristic [7] adapts a technique from AI Planning, namely *ignoring delete lists* [1]. The idea of this abstraction is based on the simplifying assumption that *every state variable, once it obtained a value, keeps that value forever*. I.e., the value of a variable is no longer an element, but a *subset* of its domain. This subset grows monotonically over transition applications – hence the name of the abstraction.

When applying the monotonicity abstraction to a system of timed automata, then each automaton will (potentially) be in several locations in a state. The system’s integer variables will have several possible values in a state. So far clocks are not included in the computation of heuristic values. If we included clocks in the obvious way, every guard or invariant involving a clock would be immediately satisfied. The reason for this is that clock value sets quickly subsume all possible time points.

Our heuristic h^{ma} assigns to each state encountered during search a heuristic value by solving an abstract problem. Such an abstract problem is obtained by applying the monotonicity abstraction to the current state. The length of a solution found in this abstraction is then used as the heuristic estimate for the state’s distance to the nearest error state. In a nutshell, an abstract solution is computed by iteratively applying all enabled transitions to the initial abstract state (the state for which we want to estimate the distance), until either the enlarged state subsumes an error state, or a fixpoint is reached. In the former case, an abstract solution can be extracted by backtracing through the state enlargement steps. In case of reaching a fixpoint, we can exclude this state from further exploration: the monotonicity abstraction induces an over-approximation, i.e. so if there is no abstract error path, then there is no real one either.

2.2 Automata-theoretic Abstraction

The second heuristic [3] aims at a close representation of the process synchronisation required to reach the error. Each process is represented as a finite-state automaton. The heuristic h^{aa} estimates the error distance $d(s)$ of a system state s as the error distance of the corresponding abstract state $\alpha(s)$ in an abstraction that approximates the full product of all process automata.

The approximation of the product of a set of automata is computed incrementally by repeatedly selecting two automata from the current set and replacing them with an abstraction of their product. To avoid state space explosion, the size of these intermediate abstractions is limited by a preset bound N : to reach a reduction to N states, the abstraction first merges bisimilar states and then states whose error distance is already high in the partial product.

In this way, the precision of the heuristic is guaranteed to be high in close proximity to the error, and can, by setting N , be fine-tuned for states further away from the error. In our experiments, fairly low values of N , such as $N = 100$, already significantly

speed up the search for the error, and therefore represent a good trade-off between cost and precision.

3 Results

We compare the performance of UPPAAL/DMC’s greedy search and UPPAAL’s randomised depth first search (rDF), which is UPPAAL’s most efficient standard search method across many examples. The results for rDF in Table 1 are averaged over 10 runs. The C_i examples stem from an industrial case study called “Single-tracked Line Segment” [6] and the M_i examples come from another case study, namely “Mutual Exclusion” [2]. An error state was made reachable by increasing an upper time bound in each example.

The results in Table 1 clearly demonstrate the potential of our heuristics. The heuristic searches consistently find the error paths much faster. Due to the reduced search space size and memory requirements, they can solve all problems. At the same time, they find, by orders of magnitude, *much* shorter error paths in *all* cases.

Table 1. Experimental results of UPPAAL’s rDF and UPPAAL/DMC’s greedy search with h^{ma} and h^{aa} . The results are computed on an Intel Xeon with 3 Ghz and 4 GB of RAM. Dashes indicate out of memory.

Exp	runtime in s			explored states			memory in MB			trace length		
	rDF	h^{ma}	h^{aa}	rDF	h^{ma}	h^{aa}	rDF	h^{ma}	h^{aa}	rDF	h^{ma}	h^{aa}
M_1	0.8	0.1	0.2	29607	5656	12780	7	1	11	1072	169	74

Other heuristics, proposed by Edelkamp et al. [4, 5] in the context of SPIN, are based on graph distances. The underlying abstraction of these heuristics preserves only edges and locations of an automata system. For an automaton a let $d(a)$ be the distance of a ’s start location to its target location. Then, the h_{max}^{gd} heuristic is defined as $\max_a d(a)$. The h_{sum}^{gd} heuristic is defined as $\sum_a d(a)$.

Note that h_{max}^{gd} and h_{sum}^{gd} are rather crude approximations of the systems semantics. For example, they completely ignore variables and synchronisation. In contrast, the h^{ma}

and h^{aa} heuristics do *not* do this. Our approximations are more costly, i.e. one call of h^{ma} or h^{aa} takes more runtime than one call of h_{max}^{gd} or h_{sum}^{gd} . The additional effort typically pays off: for example, in the case studies shown in Table 1, greedy search with $\max_a d(a)$ and $\sum_a d(a)$ performs only slightly better than rDF, and much worse than our heuristics; e.g. it cannot solve any of C_6 , C_7 , C_8 , and C_9 .

4 Outlook

The most important piece of future work is to explore the value of our tool in the abstraction refinement life cycle. The basic idea is to use heuristics to address the intermediate iterations where (spurious) errors still exist. As our results show, this has the potential to speed up the process *and* yield shorter, and thus more informative error paths. Hence, our technique for error detection will be able to help with actual *verification*.

4.1 Availability of the Tool

At http://www.informatik.uni-freiburg.de/~kupfersc/uppaal_dmc/, two Linux executables of UPPAAL/DMC are available. The first version is optimised for Intel Pentium 4 processors, the other one was compiled with default optimisation. The page also provides a short description of the used benchmarks, and *all* used model and query files.

Acknowledgments

This work was partly supported by the German Research Council (DFG) as part of the Transregional Collaborative Research Center “Automatic Verification and Analysis of Complex Systems” (SFB/TR 14 AVACS). See <http://www.avacs.org/> for more information.
