Hybrids of  
Local Search  
and Inference

Summary

Literature

# Greedy Local Search

Constraint solving techniques so far discussed:

- Inference
- Search
- Combinations of inference and search
  - ↪ improve overall performance; nevertheless worst-time complexity is high
- ⇒ approximate solutions, for example, by greedy local search methods
- ⇒ in particular of interest, when we look at optimization problems (e.g. traveling salesman problem, minimize violations of so-called soft constraints)

Summary

Literature

# A first method: greedy heuristics

- Building step by step a solution  $(v_1 \mapsto x_1, \dots, v_n \mapsto x_n)$
- Generic Algorithm:
  - $s \leftarrow \emptyset$
  - While  $s$  is not a total assignment
    - Pick a variable  $v_i$  and a value  $x_i \in D_i$ .
    - $v_i \leftarrow x_i$
  - EndWhile

Is actually backtracking without BT.

Sometimes some pretreatment are realized before the greedy part.

# Example: Christofides Algorithm

Sometimes run a greedy algorithm after a pretreatment.  
Example: the Christofides Algorithm for the TSP

Objective: Find a path going through all the nodes with minimal cost.

Summary

Literature

# Stochastic Greedy Local Search (SLS)

## Features:

- greedy, hill-climbing traversal of the search space
- in particular, no guarantee to find a solution even if there is one
- search space: states correspond to complete assignment of values to all variables of the constraint network, which are not necessarily solutions of the network
- no systematic search

# The SLS-Algorithm

**SLS** ( $\mathcal{C}$ , max\_tries, cost):

---

*Input:* a constraint network  $\mathcal{C}$ , a number of tries max\_tries, a cost function cost

*Output:* A solution of  $\mathcal{C}$  or “false”

**repeat** max\_tries times

    instantiate a complete random assignment  $\bar{a} = (a_1, \dots, a_n)$

**repeat**

**if**  $\bar{a}$  is consistent **then return**  $\bar{a}$

**else** let  $Y$  be the set of assignments that differ from  $\bar{a}$  in exactly one variable-value pair (i.e., change one  $v_i$  value  $a_i$  to a new value  $a'_i$ )

$\bar{a} \leftarrow$  choose an  $\bar{a}'$  from  $Y$  with maximal cost improvement

**endif**

**until** current assignment cannot be improved

**endrepeat**

**return** “false”

Escaping Local Minima

Random Walk Strategies

Hybrids of Local Search and Inference

Summary

Literature

# Heuristics for Escaping Local Minima

- **Tabu search**: prevent cycling over assignments of the same cost. For this, maintain a list of “forbidden” assignments, called **tabu list** (usually a list of the last  $n$  variable-value assignments). The list is updated whenever the assignment changes. Then changes to variable assignments are only allowed w.r.t. to variable-value pairs not in the tabu list.

Summary

Literature

# Random Walk

## Random walk strategy:

- combines random walk search with a greedy approach (bias towards assignments that satisfy more constraints)
- instead of making greedy moves in each step, sometimes perform a random walk step
- for example, start from a random assignment. If the assignment is not a solution, select randomly an unsatisfied constraint and change the value of one of the variables participating in the constraint.

and Wöfl

Greedy  
algorithm

Stochastic  
Greedy Local  
Search

Random Walk  
Strategies

WalkSAT  
Simulated  
Annealing

Hybrids of  
Local Search  
and Inference

Summary

Literature

## WalkSAT:

- initially formulated for SAT solving
- turns out to be very successful (in empirical studies)
- based on a two-stage process for selecting variables: in each step select first a constraint violated by the current assignment; second make a random choice between
  - a) changing the value of one of the variables in the violated constraint;
  - b) minimizing in a greedy way the **break value**, i.e., the number of new constraints that become inconsistent by changing a value

The choice between (a) and (b) is controlled by a parameter  $p$  (probability for (a))

## WalkSAT ( $\mathcal{C}$ , max\_flips, max\_tries):

*Input:* a constraint network  $\mathcal{C}$ , numbers max\_flips (flips) and max\_tries (tries)

*Output:* “true” and a solution of  $\mathcal{C}$ , or  
“false” and some inconsistent best assignment

$\bar{a}' \leftarrow$  a complete random assignment

**repeat** max\_tries times

$\bar{a} \leftarrow$  a complete random assignment

**repeat** max\_flips times

**if**  $\bar{a}$  is consistent **then return** “true” and  $\bar{a}$

**else** select a violated constraint  $R_S$  with scope  $S$

            with probability  $p$ : choose an arbitrary variable-value pair  $(x, a')$ ,  
             $x \in S, \bar{a}[x] \neq a'$

            else (with probability  $1 - p$ ): choose a variable-value pair  $(x, a')$ ,  
             $x \in S, \bar{a}[x] \neq a'$ , that maximizes the number of satisfied  
            constraints when  $x$ 's value in  $\bar{a}$  is changed to  $a'$

$\bar{a} \leftarrow \bar{a}$  with  $x \mapsto a'$

**endif**

**endrepeat**

    compare  $\bar{a}$  with  $\bar{a}'$  and retain the better one as  $\bar{a}'$

**endrepeat**

**return** “false” and  $\bar{a}'$

# Simulated Annealing

## Simulated Annealing:

- *Idea:* over time decrease the probability of doing a random move over one that maximally decreases costs. Metaphorically speaking, by decreasing the probability of random moves, we “freeze” the search space.
- At each step, select a variable-value pair and compute the change of the cost function,  $\delta$ , when the value of the variable is changed to the selected value. Change the value if  $\delta$  is not negative (i.e., costs do not increase). Otherwise, we perform the change with probability  $e^{-\delta/T}$  where  $T$  is the temperature parameter.
- If the temperature  $T$  decreases over time, more random moves are allowed at the beginning and less such moves at the end.

**Simulated Annealing**

Hybrids of Local Search and Inference

Summary

Literature

# Simulated Annealing to its best: Ant Colony Optimization

- An ant runs at random around the colony;
- If it discovers a food source, it returns more or less directly to the nest, leaving in its path a trail of pheromone;
- These pheromones are attractive, nearby ants will be inclined, with a given percentage, to follow the track;
- Returning to the colony, these ants will strengthen the route;
- If there are two routes to reach the same food source then the shorter one will be traveled by more ants;
- The short route will be increasingly enhanced, and therefore become more attractive;
- The long route will disappear because pheromones are volatile;
- Eventually, all the ants have chosen the shortest route.

# Hybrids of Local Search and Inference

SLS-algorithms can also be combined with inference methods. For example, apply SLS only after preprocessing a given CSP instance with some consistency-enforcing algorithm.

*Idea:* Can we improve SLS by looking at equivalent but more explicit constraint networks?

Note:

- there are classes of problems, e.g., 3SAT problems, which can easily be solved by a systematic backtracking algorithm, but are hard to be solved via SLS
- consistency-enforcing algorithms can change the costs associated to an arc in the constraint graph drastically: assignments near to a solution (in terms of costs) may be very far from a solution after applying inference methods

Example:

- Local search on cycle cutsets

Greedy Local  
Search

Random Walk  
Strategies

Hybrids of  
Local Search  
and Inference

Summary

Literature

# Local Search on Cycle Cutsets

**Idea** for a hybrid algorithm:

- 1 Determine a cycle cutset
- 2 Find some assignment for the cutset variables
- 3 Propagate values, i.e., find assignment for the tree variables that minimize costs (how do we do that?)
- 4 Do stochastic local search by varying the cutset variables only
- 5 Continue with step 3 if there was some improvement
- 6 Otherwise stop

Usually outperforms pure SLS, provided the cutset is small ( $\leq 30\%$ ).

## MinCostTree ( $\mathcal{C}, Y, Z, \bar{y}$ ):

---

*Input:* constraint network  $\mathcal{C}$ , cutset variables  $Y$  and tree variables  $Z$  with  $Y \cup Z = V$  and a partial assignment  $\bar{y}$  to the cutset variables

*Output:* assignment  $\bar{z}$  to the variables  $Z$  minimizing constraint violations

*Comment:*  $R_{z_i, z_j}(a_i, a_j) = 1$  if  $(a_i, a_j) \in R_{z_i, z_j}$ , otherwise it is 0.

Compute costs for  $z_i$  under  $\bar{y}$  for each  $a_i \in \text{dom}(z_i)$ :  $C_{z_i}(a_i, \bar{y})$

**foreach**  $y_i \in Y$  **do**  $C_{y_i}(\bar{y}[i], \bar{y}) \leftarrow 0$  **endfor**

**foreach**  $z_i \in Z$  going from leaves to the roots **do**

$C_{z_i}(a_i, \bar{y}) \leftarrow$

$$\sum_{z_j \text{ child of } z_i} \min_{a_j \in \text{dom}(z_j)} (C_{z_j}(a_j, \bar{y}) + R_{z_i, z_j}(a_i, a_j))$$

**endfor**

**foreach**  $z_i \in Z$  going from the roots to the leaves **do**

$\bar{z}[i] \leftarrow \arg \min_{a_i \in \text{dom}(z_i)} (C_{z_i}(a_i, \bar{y}) + R_{z_i, z_{p_i}}(a_i, a_{p_i}))$

provided  $z_{p_i}$  is the parent of  $z_i$

**endfor**

**return**  $\bar{z}$

# Properties of Stochastic Local Search

SLS algorithms . . .

- are anytime: the longer the run, the better the solution they produce (in terms of a cost function counting violated constraints)
- terminate at local minima
- cannot be used to prove inconsistency of CSP instances

However, WalkSAT can be shown to find a satisfying assignment with probability approaching 1, provided the procedure can run long enough (exponentially long) and provided such an assignment exists.
